**Method for increasing the content of sulphur compounds
and in particular of cysteine, methionine and
glutathione in plants and plants obtained**

Methionine is the first limiting essential
5 amino acid in plants, in particular the leguminous
plants which are one of the basic elements of the
animal diet. Cysteine, another sulphur-containing amino
acid, is not an essential amino acid, but can be taken
to be a limiting element for animal nutrition since
10 cysteine is derived, in animals, from methionine. In
maize, the sulphur-containing amino acids are also
limiting amino acids after lysine and tryptophan. The
reason for this is that the major storage proteins of
the seeds of these plants are lacking in these amino
15 acids. The overproduction of methionine and cysteine in
the seeds of leguminous plants (soybean, lucerne, pea,
etc.) and of maize will thus have a considerable impact
on the nutritional quality of these seeds.

So far, the increase in the nutritional
20 quality of foods derived from the seeds of leguminous
plants has been obtained by supplementation with
chemically synthesized free methionine. For example,
the average contents of methionine + cysteine in
soybean and pea are of the order of 20 mg per g of
25 protein. This content must be increased to a value of
the order of 25 mg cysteine + methionine/g of protein
to cover the dietary needs of a human adult, and to a
value of the order of 48 mg of cysteine + methionine/g

003720 126316

sub
spec
as per

of protein to cover those of pigs (De Lumen, B.O., Food Technology (1997) 51, 67-70).

The techniques for characterizing proteins enriched in sulphur-containing amino acids and the preparation of transgenic plants allowing the expression of such proteins, so as to increase the sulphur-containing amino acid content of these plants and thus their nutritive value for the animal diet, and thus to diminish the amount of synthesized methionine supplied, are now well known and described in the literature ([1] Korit, A.A. et al., Eur. J. Biochem (1991) 195, 329-334; WO 98/20133; WO 97/41239; WO 95/31554; WO 94/20828; WO 92/14822).

The enrichment in proteins with a high sulphur-containing amino acid content by such an approach remains, however, limited by the capacity of plant cells and of plants to produce the said sulphur-containing amino acids required for the synthesis of the protein. The reason for this is that plants overexpressing a protein rich in methionine and cysteine in their seed, such as for example lupins expressing 8S albumin, contain a level of free methionine and cysteine, and also of glutathione, which is lower than that of control plants ([2] Tabe, L. & Droux, M., 4th Workshop on Sulphur Metabolism, in press).

In the same way, peptides rich in sulphur-containing amino acids and having antifungal or

the said plants to resist certain fungal or bacterial attacks. Here again, the production of such peptides in the plants remains limited by the capacity of plant cells and plants to produce the sulphur-containing amino acids required for the synthesis of these peptides. The reason for this is that the expression of these peptides in the plant cell occurs to the detriment of the stock of glutathione, which is taken to be a reservoir for cysteine.

25 In plants, methionine biosynthesis is carried
out from cysteine, this same cysteine being involved in
the synthesis of glutathione.

Glutathione is a form of storage of reduced sulphur and represents 60 to 70% of the organic sulphur in the cell. Glutathione plays an important role for plants in the resistance to oxidative stress and in the elimination of toxic compounds. It thus participates in the elimination of xenobiotic compounds: heavy metals (for example) via the formation of phytochelatins and metallothionines; herbicides, via glutathione S-transferase activity; which are toxic to the plant, and in the plant's defence mechanisms against micro-organisms. By increasing a plant's cysteine content, and consequently its glutathione content, it is thus possible to modulate the plant's response to the different stresses mentioned above.

There are therefore two distinct metabolic pathways starting from cysteine, one for the preparation of methionine, the other for the preparation of glutathione (**Figure 1**) and for which the different enzymes involved are recalled below. The SAT (E1) and OASTL (E2) activities are at a metabolic crossroads between the assimilation of organic nitrogen and carbon (serine) and of inorganic sulphur (reduced sulphur from the sequence of assimilation and reduction of sulphate, shaded box). The cysteine is then incorporated into proteins, but also participates in the synthesis of glutathione and methionine. The synthesis of the carbon backbone (O-phosphohomoserine) of this latter amino acid, is derived from aspartate.

5 (cystathionine γ -synthase) is indicated in the diagram

6 ([3] Giovanelli J. in Sulphur Nutrition and Sulphur

7 Assimilation in Higher Plants, (1990) pp. 33-48;

8 [4] Chiba Y. et al. (1999), Science, 286, 1371-1374).

9 Methionine is the precursor of SAM

In plants the final steps of cysteine
15 synthesis involve the two enzymes below:

Serine + acetyl-coenzyme A \rightleftharpoons O-acetylserine + coenzyme A

20 O-acetylserine + sulphide \rightleftharpoons cysteine + acetate

E3) cystathionine γ -synthase (EC 4.2.99.9) (CGS):

25 Pi signifies inorganic phosphate.

$$\text{cystathionine} + \text{H}_2\text{O} \rightleftharpoons \text{homocysteine} + \text{pyruvate} + \text{NH}_4^+$$

E5) methionine synthase (EC 2.1.1.14) (Ms):

homocysteine + 5-methyltetrahydrofolate \rightleftharpoons methionine + tetrahydrofolate

As for the synthesis of glutathione from cysteine, it involves, successively, the two enzymes below:

E6) γ -glutamylcysteine synthetase (EC 6.3.2.2)

glutamate + L-cysteine + ATP \rightleftharpoons γ -glutamylcysteine + ADP + Pi

10 E7) glutathione synthetase (EC 6.3.2.3)

γ -glutamylcysteine + glycine + ATP \rightleftharpoons glutathione + ADP + Pi

- All these enzymes have been characterized and cloned in plants ([5] Lunn, J.E. et al., Plant Physiol. (1990) 94, 1345-1352; [6] Rolland, N. et al., Plant Physiol. (1992) 98, 927-935; [7] Droux, M. et al., Arch. Biochem. Biophys. (1992) 295, 379-390; [8] Rolland, N. et al., Arch. Biochem. (1993) 300, 213-222; [9] Ruffet, M.L. et al., Plant Physiol. (1994) 104, 597-604; [10] Ravanel, S. et al., Arch. Biochem. Biophys. (1995) 316, 572-584; [11] Droux, M. et al., Arch. Biochem. Biophys. (1995) 316, 585-595; [12] Ruffet, M.L. et al., Eur. J. Biochem. (1995) 227, 500-509; [13] Ravanel, S. et al., Biochem. J. (1996) 320, 383-392; [14] Ravanel, S. et al., Plant Mol. Biol. (1996) 29, 875-882; [15] Rolland, N. et al., Eur. J. Biochem. (1996) 236, 272-282; [16] Ravanel, S. et al., Biochem. J. (1998) 331, 639-648; [17] Droux, M. et al.,

realization

- Eur. J. Biochem. (1998) 255, 235-245; [18] ^{E6} May, M.J.,
 Leaver, C.J., Proc. Natl. Acad. Sci. USA (1994) 91,
 10059-10063; [19] ^{E7} Ullmann, P. et al., Eur. J. Biochem.
 (1996) 236, 662-669; [20] ^{E5} Eichel, J. et al., Eur. J.
 5 Biochem. (1995) 230, 1053-1058).

It is known that for cysteine synthesis, the
 E1 and E2 enzymes are present in the three compartments
 of the plant cell, that is to say, the plastids, the
 cytosol and the mitochondria (5-6, 9, 12). These three
 10 E1 enzymes are named SAT2 and SAT4 for the (putative)
 chloroplast enzyme, and SAT1 for the mitochondrial
 enzyme, and SAT3 and SAT3' (SAT52) for the cytoplasmic
 enzyme. These localization attributions are based on
 sequence analysis.

- 15 For the methionine synthesis enzymes, the
 situation is different since the E3 and E4 enzymes are
 exclusively localized in the plastids (10-11, 13-14, 16),
 while the terminal E5 enzyme is in the cytosol (20).

As for the enzymes associated with the
 20 glutathione biosynthetic pathway, they are localized
 both in the chloroplast and in the cytosol ([21] Hell,
 R. and Bergmann, L., Planta (1990) 180, 603-612).

The E3 enzyme, of the methionine synthetic
 pathway, has a K_m (substrate concentration giving the
 25 half-maximal rate) of the order of 200 μM to 500 μM for
 cysteine (10, 16, [22] Kreft, B-D. et al., Plant
 Physiol. (1994) 104, 1215-1220).

The E6 enzyme, of the glutathione synthetic pathway, also has a high K_m for cysteine, of the order of 200 μ M [21].

It has now been observed the chloroplast
5 serine acetyltransferase enzyme (**Figure 2**) and to a
lesser degree the mitochondrial SAT are inhibited by
cysteine, in contrast to the cytoplasmic enzyme (**Figure**
2), this inhibition constituting the essential limiting
factor in the synthesis of cysteine in plant cells and
10 being downstream of the methionine and glutathione.

The present invention thus consists in
increasing the level of cysteine and methionine
synthesized in the cellular compartments of plant
cells, and in particular in the chloroplast
15 compartment. Increasing the level of cysteine, the
sulphur-containing precursor of glutathione and of
methionine and its derivatives, advantageously makes it
possible to increase the level of methionine and/or of
glutathione in the plant cells and plants, and
20 subsequently to improve the production of proteins,
natural or heterologous, enriched in sulphur-containing
amino acids in the plant cells and plants, and
similarly the tolerance of the plants to different
forms of glutathione-regulated stress.

25 This increase according to the invention is
obtained by overexpressing a serine acetyltransferase
(SAT) in the plant cells and plants.

5 said method consisting in overexpressing an SAT in the
plant cells and in plants containing the said plant
cells.

10 SAT1, SAT3, SAT3' (SAT52), or of any other origin, in particular bacterial, in a native or mutant form or deleted of a fragment, and functional in the synthesis of O-acetylserine.

15 SAT, such as for example a plant SAT, for example a
chloroplast or mitochondrial SAT (SAT2, SAT4, SAT1), or
a native SAT of bacterial origin ([22] ^{bac}Nakamori et al.,
1998, Appl. Environ. Microbiol., 64, 1607-1611;
[23] ^{DKC}Takagi H. et al., 1999, Febs Lett. 452, 323-327;
20 [24] ^{DKC}Mino K. et al., 1999, Biosci. Biotechnol.
Biochem., 63, 168-179).

25 origin, made insensitive to cysteine by mutagenesis
([22] and [23], whose contents are incorporated here by
reference), or any mutant plant SAT which is functional

in the synthesis of O-acetylserine (the carbon-containing precursor for cysteine synthesis).

According to a specific embodiment of the invention, the SAT is an *Arabidopsis thaliana* SAT [12].

5 According to a first embodiment of the invention, the SAT is overexpressed in the cytoplasm of the plant cells. The SAT is either a plant cytoplasmic SAT, in particular the SAT3 (L34076) or SAT3' or SAT52 (U30298), represented by the SEQ ID NO 1 or the SEQ ID
10 NO 2, respectively, or an SAT of bacterial origin as defined above. The SAT overexpressed in the cytoplasm can also be a noncytoplasmic plant SAT, for example a chloroplast or mitochondrial SAT. These noncytoplasmic plant SATs, naturally, are expressed in the cytoplasm
15 in the form of a precursor protein comprising a signal for addressing to the cellular compartment, other than the cytoplasm, into which the mature functional SAT is released. In order to overexpress these mature functional SATs in the cytoplasm, their addressing
20 signal is removed. In this case, the SAT protein overexpressed in the cytoplasm is a noncytoplasmic plant SAT, with its signal(s) for addressing to cellular compartments, other than the cytoplasm, removed.

25 According to a specific embodiment of the invention, the noncytoplasmic SAT with its addressing signal removed is SAT1' represented by SEQ ID NO 3.

According to a second embodiment of the invention, the SAT is overexpressed in the mitochondria. The protein is advantageously expressed in the cytoplasm in the form of a signal peptide/SAT fusion protein, the mature functional SAT being released inside the mitochondria. Advantageously, the mitochondrial addressing signal peptide is made up of at least one mitochondrial addressing signal peptide from a plant protein which is located in mitochondria, such as the tobacco ATPase β -F1 subunit signal peptide [[25] Hemon P. et al. 1990, Plant Mol. Biol. 15, 895-904], or the SAT1 signal peptide represented by amino acids 1 to 63 in SEQ ID NO 4.

According to a specific embodiment of the invention, the mitochondrial SAT is SAT1 (U22964) represented by SEQ ID NO 4.

According to a third embodiment of the invention, the SAT is overexpressed in the chloroplasts of the plant cells.

The SAT will be expressed in the chloroplasts by any appropriate means, in particular by any means known to persons skilled in the art and widely described in the prior art.

According to a specific embodiment of the invention, the SAT is overexpressed in the chloroplasts by integrating into the chloroplast DNA a chimeric gene comprising a DNA sequence encoding the said SAT, under the control of 5' and 3' regulatory elements that

function in the chloroplasts. The techniques for insertion of genes into chloroplasts, such as the regulatory elements appropriate for the expression of the said genes in chloroplasts, are well known to
5 persons skilled in the art and in particular are described in the following patents and patent applications: US 5,693,507, US 5,451,513 and WO 97/32977.

According to another specific embodiment of
10 the invention, the SAT is overexpressed in the cytoplasm in the form of a transit peptide/SAT fusion protein, the function of the transit peptide being to address the SAT to which it is fused to the chloroplasts, the mature functional SAT being released
15 inside the chloroplasts after cleavage at the chloroplast membrane.

In this case, the SAT can be a chloroplast SAT of plant origin, such as SAT2 or SAT4, represented by SEQ ID NO 5 or 6, respectively.

Sw
C5
20 The SAT can also be a cytoplasmic SAT of plant origin or an SAT of bacterial origin as defined above. The cytoplasmic SATs are understood to include also noncytoplasmic SATs from which have been removed their signal for addressing to a compartment other than
25 the cytoplasm, as defined above.

The transit peptides, their structures, their methods of functioning and their use in the construction of chimeric genes for addressing a

5 the following patent applications are mentioned:

EP 189 707, EP 218 571 and EP 508 909, and the

In the fusion protein according to the invention, the SAT can be homologous or heterologous to the transit peptide. In the first case, the fusion protein is the SAT2 or the SAT4 protein expressed naturally in the chloroplasts of plant cells. In the second case, the transit peptide can be a transit peptide from an SAT2, represented by amino acids 1 to 32 of SEQ ID 5, or the transit peptide from an SAT4, represented by amino acids 1 to 30 of SEQ ID NO 6, or alternatively a transit peptide from another protein, which is located in plastids, in particular the transit peptides defined below. Plastid localization protein is understood to mean a protein expressed in the cytoplasm of plant cells in the form of a transit peptide/protein fusion protein, the mature protein being localized in the chloroplast after cleavage of the transit peptide.

25 A plant EPSPS transit peptide is, in particular, described in Patent Application EP 218,571, while a plant RuBisCO ssu transit peptide is described in Patent Application EP 189,707.

According to another embodiment of the invention, the transit peptide also comprises, between the C-terminal region of the transit peptide and the N-terminal region of the SAT a portion of sequence from the mature N-terminal region of a plastid localization protein, this portion of sequence generally comprising less than 40 amino acids from the N-terminal region of the mature protein, preferably less than 30 amino acids, more preferably between 15 and 25 amino acids.

Such a transit peptide comprising a transit peptide fused to a part of the N-terminal region of a plastid localization protein is, in particular, described in Patent Application EP 189,707, more particularly for the transit peptide and the N-terminal region of plant RuBisCO ssu.

According to another embodiment of the invention, the transit peptide also comprises, between the C-terminal region of the N-terminal region of the mature protein and the N-terminal region of the SAT, a second transit peptide from a plastid localization plant protein. Preferably, this chimeric transit peptide comprising a combination of several transit peptides, is an optimized transit peptide (OTP) made by fusing a first transit peptide with a portion of sequence from the mature N-terminal region of a protein which is located in plastids, which is fused with a second transit peptide. Such an optimized transit peptide is described in Patent Application EP 508,909,

more particularly, the optimized transit peptide comprising the sunflower RuBisCO ssu transit peptide fused to a peptide made of the 22 N-terminal amino acids of the mature maize RuBisCO ssu, fused to the
5 maize RuBisCO ssu transit peptide.

The present invention also relates to a transit peptide/SAT fusion protein in which the SAT defined above is heterologous to the transit peptide and in which the transit peptide is made of at least
10 one transit peptide from a natural plant protein which is located in plastids, as defined above.

The present invention also relates to a nucleic acid sequence encoding a transit peptide/SAT fusion protein, described above. According to the
15 present invention, "nucleic acid sequence" is understood to mean a nucleotide sequence which can be of DNA or RNA type, preferably of DNA type, in particular double-stranded, whether of natural or synthetic origin, in particular a DNA sequence in which
20 the codons encoding the fusion protein according to the invention have been optimized according to the host organism in which it will be expressed, these optimization methods being well known to persons skilled in the art.

25 A subject of the invention is also the use of a nucleic acid sequence encoding an SAT according to the invention defined above, in particular for chloroplast, mitochondrial or cytoplasmic addressing,

in a method for transforming plants, as a coding sequence allowing the modification of the cysteine, methionine, methionine derivatives, and glutathione contents of the transformed plants. This sequence can
5 of course also be used in combination with other marker gene(s) and/or coding sequence(s) for one or more other agronomic properties.

The present invention also relates to a chimeric gene (or expression cassette) comprising a
10 coding sequence as well as heterologous 5' and 3' regulatory elements capable of functioning in a host organism, in particular plant cells or plants, the coding sequence comprising at least one nucleic acid sequence encoding an SAT as defined above.

15 Host organism is understood to mean any monocellular or pluricellular higher or lower organism, into which the chimeric gene according to the invention can be introduced. They are in particular bacteria, for example *E. coli*, yeasts, in particular of the genera
20 *Saccharomyces*, *Kluyveromyces* or *Pichia*, fungi, in particular *Aspergillus*, a baculovirus, or preferably plant cells and plants.

"Plant cell" is understood to mean according to the invention any cell derived from a plant and
25 capable of constituting undifferentiated tissues such as calli, differentiated tissues such as embryos, plant portions, plants or seeds.

"Plant" is understood to mean according to the invention any differentiated multicellular organism capable of photosynthesis, in particular monocotyledonous or dicotyledonous plants, more particularly crop plants intended or not as animal feed or for human consumption, such as maize, wheat, rape, soybean, rice, sugar cane, beet, tobacco, cotton and the like.

The regulatory elements required for the expression of the a nucleic acid sequence encoding a fusion protein according to the invention are well known to persons skilled in the art according to the host organism. They comprise, in particular, promoter sequences, transcription activators, termination sequences including start and stop codons. The means and methods of identifying and selecting the regulatory elements are well known to persons skilled in the art and widely described in the literature.

The invention relates more particularly to the transformation of plants. Promoter regulatory sequences which can be used in plants, are any promoter sequence of a gene which is naturally expressed in plants, in particular a promoter which is expressed in particular in the leaves of plants such as, for example, so-called constitutive promoters of bacterial, viral or plant origin, or alternatively so-called light-dependent promoters such as that of a plant ribulose-biscarboxylase/oxygenase (RuBisCO) small

subunit gene or any suitable known promoter that can be used. Among promoters of plant origin which can be mentioned are the histone promoters as described in Application EP 0,507,698, or the rice actin promoter (US 5,641,876). Among promoters of plant virus genes which can be mentioned are that of the cauliflower mosaic (CAMV 19S or 35S), or the circovirus promoter (AU 689 311).

It is also possible to use a promoter regulatory sequence which is specific for regions or tissues specific to plants, and more particularly seed-specific promoters ([26] Datla, R. et al., Biotechnology Ann. Rev. (1997) 3, 269-296), in particular the napin (EP 255,378), phaseolin, glutenin, zein, helianthinin (WO 92/17580), albumin (WO 98/45460), oelosin (WO 98/45461), SAT1 or SAT3 (WO 99/20275) promoters.

According to the invention, it is also possible to use, in combination with the regulatory promoter sequence, other regulatory sequences which are situated between the promoter and the coding sequence, such as transcription enhancers, such as, for example the translational enhancer of tobacco mosaic virus (TMV) described in Application WO 87/07644, or of tobacco etch virus (TEV) described by Carrington & Freed.

Regulatory termination or polyadenylation sequences which can be used, are any corresponding

sequence of bacterial origin, such as for example the nos terminator of *Agrobacterium tumefaciens*, or alternatively of plant origin, such as for example a histone terminator as described in Application

5 EP 0,633,317.

The present invention also relates to a cloning and/or expression vector for the transformation of a host organism containing at least one chimeric gene as defined above. This vector comprises, besides
10 the chimeric gene above, at least one origin of replication. This vector can be a plasmid, a cosmid, a bacteriophage or a virus, which has been transformed by introducing a chimeric according to the invention. Such transformation vectors, according to the host organism
15 to be transformed, are well known to persons skilled in the art and widely described in the literature. For the transformation of plant cells or plants, a virus, moreover containing its own elements of replication and expression, can, in particular, be used to transform
20 developed plants. Preferably, the transformation vector of plant cells or plants according to the invention is a plasmid.

For the transformation of host organisms, the chimeric gene according to the invention can be used in
25 combination with a selection marker gene, either in the same vector, the two genes being combined in a convergent, divergent or colinear manner, or alternatively in two vectors used simultaneously for

Among genes encoding selection markers which can be mentioned are antibiotic-resistance genes, genes which impart tolerance to herbicides (bialaphos, glyphosate or isoxazoles), genes encoding easily identifiable enzymes such as the GUS enzyme (or GFP, "Green Fluorescent Protein"), or genes encoding pigments or enzymes which regulate the production of pigments in the transformed cells. Such selection marker genes are in particular described in Patent Applications EP 242 236, EP 242 246, GB 2 197 653, WO 91/02071, WO 95/06128, WO 96/38567 or WO 97/04103.

The subject of the invention is also a method for transforming host organisms, in particular plant cells, by integration of at least one nucleic acid sequence or one chimeric gene as defined above, which transformation may be obtained by any known appropriate means, widely described in the specialist literature and in particular the references cited in the present application, more particularly by the vector according to the invention.

25 One series of methods consists in bombarding
cells, protoplasts or tissues with particles to which
the DNA sequences are attached. Another series of
methods consists in using, as a means of transferring

into the plant, a chimeric gene inserted into an *Agrobacterium tumefaciens* Ti plasmid or an *Agrobacterium rhizogenes* Ri plasmid. Other methods can be used, such as microinjection or electroporation, or
5 alternatively direct or PEG precipitation. Persons skilled in the art will choose the appropriate method according to the nature of the host organism, in particular of the plant cell or of the plant.

The subject of the present invention is also
10 the host organisms, in particular plant cells or plants, which are transformed and which contain a chimeric gene defined above.

The subject of the present invention is also the plants containing transformed cells, in particular
15 the plants regenerated from the transformed cells. The regeneration is obtained by any appropriate method which depends on the nature of the species, as for example described in the above references. Patents and patent applications which are mentioned for the methods
20 of transforming plant cells and of regenerating plants are, in particular, the following: US 4,459,355, US 4,536,475, US 5,464,763, US 5,177,010, US 5,187,073, EP 267,159, EP 604,662, EP 672,752, US 4,945,050, US 5,036,006, US 5,100,792, US 5,371,014, US 5,478,744,
25 US 5, 179,022, US 5,565,346, US 5,484,956, US 5,508,468, US 5,538,877, US 5,554,798, US 5,489,520, US 5,510,318, US 5,204,253, US 5,405,765, EP 442,174,

EP 486,233, EP 486,234, EP 539,563, EP 674,725,
WO 91/02071 and WO 95/06128.

The subject of the present invention is also
the transformed plants derived from the cultivation
5 and/or the crossing of the above regenerated plants, as
well as the seeds of the transformed plants.

The transformed plants which can be obtained
according to the invention can be of monocotyledonous
type, such as for example cereals, sugar cane, rice and
10 maize, or of dicotyledonous type, such as for example
tobacco, soybean, rape, cotton, beet, clover, etc.

The plants transformed according to the
invention can contain other genes of interest, which
confer novel agronomic properties on the plants. Among
15 genes conferring novel agronomic properties on the
transformed plants which can be mentioned are genes
conferring tolerance to certain herbicides, those
conferring tolerance to certain insects, and those
conferring tolerance to certain diseases. Such genes
20 are in particular described in Patent Applications
WO 91/02071 and WO 95/06128. Mention may also be made
of genes which modify the composition of the modified
plants, in particular the content and quality of
certain essential fatty acids (EP 666,918), or
25 alternatively the content and quality of proteins, in
particular in the leaves and/or seeds of the said
plants. In particular, genes encoding proteins enriched
in sulphur-containing amino acids are cited([1];

WO 98/20133; WO 97/41239; WO 95/31554; WO 94/20828;
WO 92/14822; US 5,939,599, US 5,912,424). The function
of these proteins enriched in sulphur-containing amino
acids is also to trap and store surplus cysteine and/or
5 methionine, making it possible to avoid any problems of
toxicity linked to an overproduction of these sulphur-
containing amino acids, by trapping them.

Mention may also be made of genes encoding
peptides rich in sulphur-containing amino acids and
10 more particularly rich in cysteine, the said peptides
also having antibacterial and/or antifungal activity.
More particularly, plant defensins are mentioned, as
well as lytic peptides of any origin, and more
particularly the following lytic peptides: androctonin
15 (WO 97/30082 and WO 99/09189), drosamicin
(WO 99/02717), thanatin (WO 99/24594) or heliomicin
(WO 99/53053).

These other genes of interest can be combined
with the chimeric gene according to the invention
20 either by conventional crossing of two plants each
containing one of the genes (the first being the
chimeric gene according to the invention and the second
being the gene encoding the protein of interest), or by
transforming the plant cells of a plant containing the
25 gene encoding the protein of interest, with the
chimeric gene according to the invention.

The following examples illustrate the invention, without, however, looking to limit its scope.

All of the methods or operations described below in these examples are given by way of examples and correspond to a choice made from the different methods available to arrive at the same result. This choice has no bearing on the quality of the result and consequently, any adapted method can be used by persons skilled in the art to arrive at the same result. Most of the methods for engineering DNA fragments are described in "Current Protocols in Molecular Biology" Volumes 1 and 2, Ausubel F.M. et al, published by Greene Publishing Associates and Wiley Interscience (1989) or in Molecular Cloning, T. Maniatis, E.F. Fritsch, J. Sambrook, 1982.

The contents of all the references cited in the above description and in the following examples are incorporated into the text of the present patent application by reference.

Example 1. Demonstration of the inhibition of chloroplast serine acetyltransferase from pea (*Pisum sativum*) leaves by cysteine

The three subcellular compartments corresponding to the cytosol (preparation from a subcellular fractionation of pea protoplasts, [12]), to mitochondria and to chloroplasts are prepared from pea

5

10

The serine acetyltransferase activity is measured by high performance liquid chromatography (HPLC), by assaying the O-acetylserine formed during the course of the reaction (reaction 1), after derivatization with orthophthalaldehyde (OPA). A defined quantity of the protein extract, corresponding to the cytosol and to the different soluble fractions of chloroplasts (stroma) and of mitochondria (matrix), is desalted on a PD10 column (Pharmacia) pre-equilibrated in a buffer containing 50 mM Hepes-HCl, pH 7.5 and 1 mM EDTA. The enzyme reaction is carried out in the presence of 50 mM Hepes-HCl, pH 7.5, 1 mM dithiothreitol, 10 mM L-serine, 2.5 mM acetyl-CoA, in a 100 μ l reaction volume, at 25°C. After 10 to 15 minutes' incubation, the reaction is stopped by addition of 50 μ l of 20% (W/V) trichloroacetic acid. The proteins thus precipitated are then eliminated by centrifugation for 2 min at 15,000 g. The supernatant, which contains the reaction product (OAS), is mixed with 500 μ l of a derivatization solution (54 mg of OPA dissolved in 1 ml of absolute ethanol, 9 ml of a 400 mM solution of borate-NaOH, pH 9.5, and 0.2 ml of 14 M

β-mercaptoethanol) and incubated for 2 min. A fraction of this mixture (20 µl) is injected onto a reverse phase column (3.9 × 150 mm, AccQ Tag C₁₈ column, Waters) which is connected to an HPLC system. The buffers used to elute the compounds derivatized by OPA are: Buffer A, 85 mM sodium acetate, pH 4.5 and 6% (V/V) acetonitrile, pH 4.5; Buffer B, 60% (V/V) acetonitrile in water. The O-acetylserine, which has been derived by OPA, is eluted with a continuous linear gradient of buffer B in buffer A, of 25 to 70% (V/V), and is detected by fluorescence at 455 nm (excitation at 340 nm). The retention time of O-acetylserine, under our conditions, is of the order of 6.2 min., and the amount of product which is formed in the enzyme assays is quantified from a standard curve which is obtained for O-acetylserine. The enzyme assays were optimized in order to respect the optimum pH of the reaction, the linearity with time, and in order to operate under saturating conditions of substrates.

20

Effect of cysteine on serine acetyltransferase activity of pea leaves

Incubation (2 min) is carried out in the presence of protein extract (cytosol, matrix, and stroma), and in the presence of increasing concentrations of L-cysteine (from 0 to 1 mM), before adding saturating concentrations of the serine acetyltransferase substrates, L-serine (10 mM) and

5 If free cysteine (from 0 to 1 mM, **Figure 2**)
is added to the different assays, a very strong
inhibition of chloroplast serine acetyltransferase
activity is observed (inhibition constant of the order
of 30 μ M). Mitochondrial serine acetyltransferase
10 activity is inhibited, but at higher concentrations of
cysteine (inhibition constant of the order of 300 μ M).
On the other hand, cytosolic serine acetyltransferase
activity is insensitive to inhibition by cysteine up to
concentrations of the order of 1 mM cysteine
15 (**Figure 2**). This result proves, therefore, that only
chloroplast serine acetyltransferase activity, thus the
enzyme associated with the sulphate assimilation
pathway, is inhibited by the final product, L-cysteine.

Table I: Determination of the specific activities and IC_{50} values of cysteine for each of the serine acetyltransferase isoforms.

Serine acetyltransferase (<i>Pisum sativum</i>)		
	Specific activity $nmol\ OAS \cdot min^{-1} \cdot mg^{-1}$	IC_{50} L-cysteine μM
Stroma	0.93 ± 0.2	33.4 ± 8
Matrix	10 ± 2	283 ± 50
Cytosol	0.83 ± 0.3	no inhibition

5

The concentration of L-cysteine which makes it possible to obtain 50% inhibition (IC_{50}) under standard reaction conditions, and which is calculated for different enzyme preparations, is represented in

10 Table I. Determination of the serine acetyltransferase enzyme activity and of the IC_{50} is carried out for 9 different experiments (on stroma), and for 3 experiments for the cytosolic extracts and 3 for the mitochondrial extracts. Similarly, activity of

15 chloroplast serine acetyltransferase from spinach leaves is cysteine-sensitive. Conversely, in *Arabidopsis thaliana*, only the activity of the isoform associated with the cytosolic compartment seems to be controlled by the level of cysteine ([27] Noji M. et

20 al. 1998, J. Biol. Chem. 273, 32739-32745; [28] Inoue K. et al. 1999, Eur. J. Biochem. 266, 220-227). For

these authors, the activity associated with the chloroplast compartment is cysteine-insensitive. It would seem, therefore, that inhibition of the chloroplast serine acetyltransferase activity by cysteine is a plant-specific phenomenon, but, in particular, is very pronounced in leguminous plants, such as pea.

Study of the mode of inhibition of serine

10 acetyltransferase activity by cysteine

The enzyme reaction rate was determined for fixed concentrations of cysteine (0 μ M; 10 μ M; 20 μ M; 40 μ M; 60 μ M and 100 μ M), by varying either the L-serine concentration or the acetyl-CoA concentration, for saturating concentrations of the second co-substrate. For each of the kinetics obtained, the affinity of the enzyme for these substrates does not seem to be affected, but, on the other hand, the maximum reaction rate is modified. The more the concentration of L-cysteine increases, the more the rate of O-acetylserine synthesis decreases. For each of the conditions analysed, the inhibition constant K_i was estimated to be of the order of 30 (± 2.2) μ M (variable substrate: serine), and 22 (± 2) μ M (variable substrate: acetyl-CoA). We were able to show that cysteine is a non-competitive type of inhibitor of serine acetyltransferase activity and that, moreover, it is an allosteric type inhibitor (Hill constant of the order

of $1.6 \pm 0.3 \mu\text{M}$), using conventional kinetics equations ([29] Segel, I.H. (1995), John Wiley and Sons, New York). These results indicate that inhibition of the chloroplast enzyme takes place at a site other than the active site, which moreover, does not exist in the serine acetyltransferase isoform which is present in the cytosol.

These inhibition constants are consistent with the cysteine concentration determined for pea chloroplasts of $40 \pm 10 \mu\text{M}$ (2 nmol/mg chlorophyll), a value which is calculated for a stromal compartment volume of the order of 35 to 65 μl per mg of chlorophyll.

15 **Dissociation of the bi-enzymatic complex, cysteine synthase, by cysteine**

The serine acetyltransferase of the plant cell, like its bacterial homologue, forms an enzymatic complex with *O*-acetylserine (thiol) lyase, the enzyme which catalyses the condensation of reduced sulphur with *O*-acetylserine. This bi-enzymatic complex is called cysteine synthase. All of the serine acetyltransferase of the chloroplast exists in a form complexed with *O*-acetylserine (thiol) lyase, while the majority of the *O*-acetylserine (thiol) lyase is in the free form. The distribution of each of these enzymes in each of the subcellular compartments of pea leaves is described in Table II.

	Serine acetyl- O-acetylserine transferase (thiol) lyase		
	Specific activity (mU/mg)		OASTL/SAT Ratio
Stroma	0.85	260	306
Matrix	12	50	4
Cytosol	0.90	180	200

The ratio of O-acetylserine (thiol) lyase (OASTL) activity to serine acetyltransferase (SAT) activity reflects the large excess of OASTL over SAT. In particular in the stroma (chloroplast), where the assimilation and reduction of sulphate takes place, and in the cytosol, 95% of the OASTL activity is in the free form. These conditions are necessary for optimal synthesis of cysteine [14]. The cysteine synthase complex is composed of a serine acetyltransferase tetramer and two O-acetylserine (thiol) lyase dimers. O-Acetylserine, the reaction product of serine acetyltransferase, dissociates this holoenzymatic complex, and sulphur tends to stabilize it [14]. These protein-protein interactions within the complex confer novel properties on each of the enzymes; in particular serine acetyltransferase acquires novel catalytic

properties compared to the free form. Moreover, complexed O-acetylserine (thiol) lyase is inactive in cysteine synthesis, and only the free form (in excess in the cell) catalyses cysteine synthesis [14].

5 A chloroplast (*Pisum sativum*) fraction, pre-incubated in the presence of an optimal concentration of cysteine (0.1 mM), which inhibits serine acetyltransferase (see Figure 2), then undergoes gel filtration chromatography which allows the separation
10 of molecules according to their molecular mass. Under these conditions the cysteine synthase complex dissociates into serine acetyltransferase tetramers and O-acetylserine (thiol) lyase dimers. Chloroplast serine acetyltransferase in its free form is still sensitive
15 to inhibition by cysteine. To refine this result and to confirm that inhibition of the enzyme is not dependent upon interaction with OASTL, a serine acetyltransferase was partially purified from pea chloroplasts, by ion exchange chromatography followed by molecular
20 filtration chromatography carried out in the presence of O-acetylserine (1 mM), a condition which leads to dissociation of the complex.

The serine acetyltransferase fraction thus free of contamination by O-acetylserine (thiol) lyase
25 is incubated in the presence of increasing concentrations of cysteine under the conditions described in Table I and **Figure 2**. The calculated IC_{50} is of the order of 15 ± 3 micromolar and is

comparable to the value obtained above for the enzyme under chloroplast conditions (see Table I). This latter result makes it possible to establish a model to explain the inhibition of chloroplast serine acetyltransferase. In **Figure 3**, the tetrameric form of serine acetyltransferase (SAT) is depicted by the grey circles and the O-acetylserine (thiol) lyase (OASTL) dimer by the black circles. The functional cysteine synthase complex in the cell is depicted by the combination of the two molecular populations. In the presence of cysteine, the cysteine synthase complex binds cysteine, which modifies the protein-protein interactions within the cysteine synthase complex, and leads to dissociation into SAT tetramers and OASTL dimers. The SAT thus in its free form is therefore sensitive to cysteine, and it is known that this structure has a tendency to form aggregates (apart from the cysteine synthase complex) whose effect is to cause a loss of its activity [14].

20

Example 2. Isolation and characterization of a gene encoding a putative cytoplasmic serine acetyltransferase isoform (SAT3) [12]

In this example the procedure described on page 502 of Ruffet et al. [12], is taken up, in particular the chapters described under the headings "Bacterial strain and growth conditions" and "Isolation

10 **Example 3. Overexpression and purification of SAT3 in**
Escherichia coli

The defined protocol for overexpression of the enzyme in *E. coli* makes it possible to purify the enzyme in its free form or complexed with plant O-acetylserine (thiol) lyase, the cysteine synthase complex [14]. Using the purified proteins, the effect of cysteine on serine acetyltransferase activity was analysed by a spectrophotometric assay based on the consumption of acetyl-CoA during reaction 1, as a function of incubation time. This analysis is carried out in a medium (1 ml) containing 50 mM Hepes-HCl, pH 7.5, 2 mM L-serine and 0.2 mM acetyl-CoA. The reaction is followed by measuring the decrease in absorbance at 232 nm (molecular extinction coefficient of 4200 M⁻¹cm⁻¹) ([30] Kredich, N.M. et al., J. Biol. Chem. (1969) 244, 2428-2439). We were able to show that this isoform (SAT3) in its free form or complexed with O-acetylserine (thiol) lyase, is cysteine-insensitive.

This result allows us to confirm that this cDNA (L34076, **Figure 4**) encodes a cytosolic serine acetyltransferase, since the amino acid composition of the N-terminus does not have the characteristics of transit peptides, and moreover, since this serine acetyltransferase is cysteine-insensitive. This latter result is similar to observations which have been obtained for the cytosolic serine acetyltransferase activity of pea leaves (**Figure 2** and Table I).

10

Example 4. Isolation and characterization of a gene encoding a cytoplasmic serine acetyltransferase isoform (SAT3') (U30298)

The procedure of Example 3 is repeated, using oligonucleotides 3 and 4 below:

Oligo 3: 5'GAGAGAGGAT CCTCTTATCG CCGCGTTAAT ATGCCACCGG
CCGGAGAACTC C 3'
Oligo 4: 5'GAGCCTTACC AGTCTAATGT AGTATATTTC AACCTCGAGA
GAGAG 3'

A gene is isolated which encodes an acetyltransferase (U 30298), and is represented in **Figure 5** (SEQ ID NO 2). Analysis of the primary sequence showed the presence of strong similarity with the sequence of the bacterial enzyme (51.6% homology and 42.6% identity). The N-terminal structure (absence of the conditions necessary for organelle addressing) indicates that this isoform is located in the cytosol. On the other hand, it is given as being cysteine-

sensitive [27]. This result differs from the data
 obtained from pea leaves (and from spinach leaves), in
 the sense that the cysteine regulation site seems to be
 confined to the cytosol in *A. thaliana* [27]. Moreover,
 it would seem that *A. thaliana* has at least two
 cytosolic isoforms: SAT3 (Example 3) and SAT3' (or
 U30298, Example 4). Unlike the SAT3 gene, the gene
 corresponding to **SAT3'** has an intron.

10 **Example 5. Isolation and characterization of genes
 encoding a serine acetyltransferase isoform (SAT1')**

The procedure described in Example 3 is
 repeated for the present example.

A gene encoding a serine acetyltransferase
 15 (L78443), which is represented in **Figure 6** (SEQ ID
 NO 3), was isolated by functional complementation of an
Escherichia coli strain deficient in serine
 acetyltransferase activity [12]. Analysis of the
 primary sequence shows strong similarity with the
 20 sequence of the bacterial enzyme (52.7% homology and
 39% identity).

The following primers were used to amplify
 the nucleotide sequence and to clone it into the vector
 which is used for transforming tobacco plants (in bold
 25 characters in **Figure 3**):

Sub C(12)

13

5 A second gene is obtained which encodes a putative mitochondrial serine acetyltransferase (U22964), and is represented in **Figure 7** (SEQ ID NO 4), by repeating the same procedure, using oligo 7 to replace oligo 5 as the 5' primer.

10

The N-terminus of the amino acid sequence of the SAT1 isoform has the characteristics of organelle (mitochondrion or chloroplast) addressing peptides. Localization in the mitochondrion was recently confirmed by constructing a fusion protein which includes the 5' portion and "green fluorescent protein" (5'SAT1-GFP) and by transforming *Arabidopsis thaliana* plants [27]. Neither the SAT1' gene (L78443) nor the SAT1 gene (U22964), like its homologue (SAT3), has introns.

Example 6. Overexpression and purification of SAT1 in *Escherichia coli*. Localization of this isoform in *A. thaliana*

The defined protocol for overexpression of the enzyme in *E. coli* makes it possible to purify the enzyme (in its transit peptide-lacking form, SAT L78443) in its free form or complexed with plant *O*-acetylserine (thiol) lyase, the cysteine synthase complex [14]. Using the purified proteins, the effect of cysteine on serine acetyltransferase activity was analysed by spectrophotometric assay, based on the consumption of acetyl-CoA during reaction 1, as a function of incubation time (see Example 3). Analysis was also carried out by HPLC assay of the reaction product (OAS) (see Example 1). We were able to show that this isoform (SAT1'), in its free form or complexed with *O*-acetylserine (thiol) lyase, is cysteine-insensitive. This latter result parallels the observations obtained for pea leaf mitochondrial serine acetyltransferase activity (**Figure 2** and Table I), the latter being inhibited at non-physiological concentrations of cysteine.

Using a preparation of mitochondria obtained from pea leaves or from protoplasts from cell cultures, localization in the mitochondrion was confirmed for this isoform.

A mitochondrial fraction lacking in plastid and in cytosolic contaminants was obtained by using the

See C14

protocol defined for pea leaf mitochondria [12]. The molecular mass of the polypeptide as revealed by antibodies raised against the peptide [-TKTLHTRPLLEDLDR-] (see SAT1 amino acid sequence), is of the order of 34,000 daltons, a value which is in agreement with the mass of the protein as obtained using sequence analysis programs for predicting cleavage sites.

10 **Example 7. Isolation and characterization of genes encoding a serine acetyltransferase isoform (SAT2)**

The procedure described for Example 3 is repeated for the present example.

A gene which encodes a serine acetyltransferase (L78444), represented in **Figure 8** (SEQ ID NO 5), was isolated by functional complementation of an *Escherichia coli* strain deficient in serine acetyltransferase activity [12]. Analysis of the primary sequence showed the presence of strong similarity with the sequence of the bacterial enzyme (49.5% homology and 35.4% identity).

The following primers were used to amplify the nucleotide sequence and to clone it into the vector which was used to transform tobacco plants (in bold characters in **Figure 8**):

Sub C167
Oligo 8 : 5' GAGAGAGGAT CCGACAAGTT GGCATAATTT
ATGGTGGATC TATCTTCCT 3'

Oligo 9 : 5' CCTGTGTGAT TGTCGTGTAG TACTCTAGAA
ACTCGAGAGA GAG 3'

These primers make it possible to introduce a
5' *Bam*H1 restriction site (GGATCC) and a 3' *Sac*I
restriction site (GAGCTC).

- 5 Analysis of the N-terminal portion of the
sequence shows the presence of characteristics for
addressing of the protein to an organelle
(mitochondrion or chloroplast). Unlike the other
isoforms described above, the SAT2 gene is complex and
10 has several introns. Comparing SAT2 sequences with its
homologues from *A. thaliana*, from plants and from other
organisms, leads to the assumption of a prokaryotic
origin (**Figure 10**). Moreover, analysis of the
N-terminal sequence using the chloroP program
15 [<http://www.cbs.dtu.dk/services/chlorP/>], indicates a
high probability of the presence of a chloroplast-type
transit peptide.

**Example 8. Isolation and characterization of genes
20 encoding a serine acetyltransferase (SAT4) isoform**

Sub C17
A gene which encodes a serine
acetyltransferase (SAT4), represented in **Figure 9** (SEQ
ID NO 6), was isolated by functional complementation of
an *Escherichia coli* strain deficient in serine
25 acetyltransferase activity [12]. Analysis of the

primary sequence showed the presence of strong similarity with the sequence of the bacterial enzyme (44.5% homology and 32% identity).

The following primers were used to amplify the nucleotide sequence and to clone it into the vector which was used for transforming tobacco plants:

Oligo 10: 5' GAGAGAGGAT CCGACAAGTTGG CATAATTTAT GGCTTGTATA
AACGGCGAGA ATCGTGATTT TTCTT 3'

Oligo 11: 5' TACCTCGTAC CACTCAGAAC TCTAGAACT CGAGAGAGAG3'

These primers make it possible to introduce a 5' *Bam*HI restriction site (GGATCC) and a 3' *Sac*I restriction site (GAGCTC).

Analysis of the N-terminal portion sequence shows the presence of characteristics for addressing of the protein to an organelle (mitochondrion or chloroplast). The SAT4 gene, like that of SAT2, is complex and has several introns. Comparing SAT4 sequences with its homologues from *A. thaliana*, from plants and from other organisms, leads to the assumption of a prokaryotic origin (**Figure 10**). Moreover, analysis of the N-terminal sequence using the chloroP program

[<http://www.cbs.dtu.dk/services/chlorP/>], indicates a high probability of the presence of a chloroplast-type transit peptide. **Figure 10** represents the sequence comparison and was carried out using the Clustaw program (Vector NTI software). SAT2 and SAT4 are closer to the prokaryotic SATs than are SAT3, SAT1 and SAT52.

Moreover, the branch also comprises an SAT from red alga (AB00848), which has been identified as a cysteine-sensitive protein located in the chloroplast ([32] Toda et al., 1998, Biochim. Biophys. Acta 1403, 72-84). SAT4 is identified as being on chromosome 4 (Bac clone F8D20, access number AL031135).

Example 9. Constructs used for transforming tobacco plants of the small Havana variety

Transgene expression in leaves

Transformation of tobacco plants is carried out through *Agrobacterium tumefaciens* EHA105, which contains the pBI121 vector (Clontech) (Figures 11 and 12).

SAT3 (or SAT1' or any cysteine-insensitive SAT)

To obtain expression of the SAT3 (SEQ ID NO 1) of Example 2 in the chloroplast (Figure 11), an extension which allows addressing to this compartment is introduced 5' of the cDNA. For this, the optimized transit peptide previously described is used.

A kanamycin-resistance gene (NPTII) which encodes neomycin phosphotransferase, and which is used as a selection marker for transforming tobacco, is cloned between the left (LE) and right (RE) edges of the t-DNA. Expression of the NPTII gene is under the control of the promoter and of the terminator of *A. tumefaciens* nopaline synthase. Downstream, the

β -glucuronidase gene which has been cloned between the unique *Bam*H1 and the unique *Sac*I sites, is under the control of the cauliflower mosaic virus (CaMV) 35S promoter and the nopaline synthase gene polyadenylation signal from the Ti plasmid. The OTP-SAT3 construct is inserted between the *Xho* and *Sac*I sites of the vector, from which has been deleted the β -glucuronidase gene (Figure 11).

SAT1, SAT3, SAT3', SAT2, SAT4 or any SAT

To obtain SAT expression in any of the subcellular compartments (cytosol, mitochondrion or chloroplast), the transgene is introduced into the appropriate vector, which is described in Figure 12.

A kanamycin-resistance gene (NPTII) which encodes neomycin phosphotransferase, and which is used as a selection marker for transforming tobacco, is cloned between the left (LE) and right (RE) edges of the t-DNA. Expression of the NPTII gene is under the control of the promoter and of the terminator of *A. tumefaciens* nopaline synthase. Downstream, the β -glucuronidase gene which has been cloned between the unique *Bam*H1 and the unique *Sac*I sites, is under the control of the cauliflower mosaic virus (CaMV) 35S promoter and nopaline synthase gene polyadenylation signal from the Ti plasmid. The gene encoding the SAT is inserted between the *Bam*H1 and *Sac*I sites of the vector, from which has been deleted the β -glucuronidase gene (Figure 12).

Transgene expression in seeds

A construct similar to that shown in **Figures 11 or 12** is prepared with the aim of obtaining specific expression of the transgene in the seeds. This strategy may be important since seeds make up the main contribution to the animal diet. For this, the constitutive tobacco mosaic promoter is replaced with a promoter which allows specific expression of the transgene during the setting up of the seeds' stocks.

10

Example 10. Transformation of tobacco

Young leaves of tobacco plants (aged from 3 to 4 weeks) whose surface is sterilized with a 10% (V/V) solution of bleach for 10 min then rinsed with sterile water, are cut up with a punch (30 discs per construct). 20 ml of a 48-hour culture of *Agrobacterium tumefaciens* EHA105 (containing the pBI121 vector modified according to the invention) are centrifuged and then resuspended in 4 ml of a 10 mM solution of MgSO_4 . The foliar discs are incubated for a few minutes in the solution of agrobacteria, then transferred to MS medium (Sigma M-5519) supplemented with 0.05 mg/l of α -naphthaleneacetic acid (NAA, Sigma), 2 mg/l of 6-benzylaminopurine (BAP) and 7 mg/l of phytoagar, for 2 to 3 days. The foliar discs are then transferred to an identical medium to which are added 350 mg/l of cefotaxin (bacteriostatic) and 75 mg/l of kanamycin (selection agent). After 2 weeks, discs on which have

005722" rec 94060

developed calli as well as young shoots, are subcultured in identical medium in order to accelerate growth of the shoots. A week later, the green shoots are excised and transferred into the same medium, without hormone, in order to allow the development of roots, this for about 2 weeks, at the end of which the young plants are transferred into earth and cultivated in a hothouse.

Example 11. Analysis of results for SAT3 and SAT1' (L78443) (truncated form of the SAT1 U22964) transgenic plants and controls

The impact of the expression of SAT3, SAT1' or OTP-SAT3 in leaves or in seeds of tobacco plants is analysed as regards the content of sulphur compounds; cysteine, methionine (and derivatives such as S-methylmethionine or SMM) and glutathione. The cysteine and glutathione are evidenced by the method of Fahey ([33] Fahey, R.C. and Newton, G.L. Methods Enzymol. (1987) 143, 85-96), after derivatization of the compounds by thiolite (mBBR from Calbiochem) and separation by high performance liquid chromatography (HPLC) [33]. The free methionine and SMM are assayed by the methods for assaying free amino acids after extraction, derivatization with ortho-phthalaldehyde, and separation by HPLC ([34] Brunet, P. et al., J. Chrom. (1988) 455, 173-182). The serine acetyltransferase activity is measured as described in

the methodology for assay of formed O-acetylserine, by the HPLC technique, or by the method of coupling in the presence of an excess of O-acetylserine (thiol) lyase [12], [14]. The SAT transgene activity in transformed
5 plants (i.e. *in vivo*) is revealed by assaying the O-acetylserine, which is produced during activity of the enzyme and is transiently accumulated in the cell.

The O-acetylserine in the plant extracts is assayed following the protocol below.

10 After crushing tobacco leaves to a fine powder in liquid nitrogen, the extracts are taken up in 0.1 M hydrochloric acid (1 ml/100 mg of powder). After an incubation period of about 10 min, the debris is eliminated by centrifugation for 15 min at 15,000 g. A
15 fraction of the obtained supernatant, containing the free amino acids, is derivatized for 1 min at 25°C in the presence of a solution of ortho-phthalaldehyde (solution containing 54 mg of ortho-phthalaldehyde, 10% methanol, 90% sodium borate, 400 mM, pH 9.5, and 0.2 ml
20 of β -mercaptoethanol). The OPA-amino acid derivatives are separated by reverse phase chromatography on a UPHDO-15M column (0.46 \times 150 mm - Interchim) connected to an HPLC system (Waters). The buffers used to carry out the elution are, buffer A: 85 mM sodium acetate, pH
25 4.5 supplemented with acetonitrile to 6% final; buffer B: 60% acetonitrile in water. Separation of the derivatives is carried out according to the gradient
(1 ml/min): 0 min, 30% B in A; 8 min, 60% B in A;

9 min, 80% B in A; 10 min, 100% B; 12 min, 100% B. At the column exit, the fluorescence emitted by the derivatives is measured at 455 nm after excitation at 340 nm (SFM25 fluorimeter, Kontron).

5 The retention time of *O*-acetylserine under our experimental conditions is 9.5 min. The identity of the peak corresponding to *O*-acetylserine is confirmed by co-elution with a known quantity of the pure product. Moreover, a second control is carried out to
10 confirm the position of *O*-acetylserine in the various analyses. The samples, before incubation with OPA, are treated with NaOH at a final concentration of 0.2 M. Under these conditions, the acetate group in the OH position on serine is transferred to the amine group,
15 thus allowing the formation of *N*-acetylserine. This latter compound is no longer detected under our experimental conditions and thus leads to the disappearance of the peak which initially corresponded to *O*-acetylserine.

20 Plants transformed with an SAT transgene were preselected with kanamycin, and run to seed. Control plants (PBI, three independent lines which contain the transforming vector and a GUS cassette) are treated in an identical way. Analyses of the plants comprise: 1;
25 demonstration of insertion of the transgene into the genome by PCR, using the 5' primer and the 3' primer which correspond to the SAT which is used for the transformation; 2, demonstration of the messenger by

analysis of messengers using probes which correspond to the SAT transgenes used for transforming the plants according to known techniques; 3, demonstration of enzyme activity associated with SAT protein according to methods described in the literature [14], and demonstration of transgene localization; 4, assay of the product of the SAT reaction, i.e. O-acetylserine (OAS), in transformed plants; 5, assay of cysteine and its direct derivatives, of glutathione and of methionine (and its methylated derivatives); 6, analysis of total amino acid composition of the plants and seeds which are associated with each of the transgenes obtained (free amino acids and amino acids linked to proteins), according to traditional techniques; 7, analysis of the impact of overexpressing SAT activity in plant cells, on the amount of enzyme activity which is associated with the sequence of assimilation of sulphur (sulphate transporters, ATP-sulphurylase, APS reductase, sulphite reductase and in particular O-acetylserine (thiol) lyase, the enzyme which is directly associated with SAT activity in cysteine synthesis [14]. Moreover, the enzymes associated with the synthetic pathway of methionine and the synthetic pathway of glutathione, are analysed in order to understand the impact of the cysteine content on the metabolism associated with glutathione synthesis and methionine synthesis.

Expression of the *Arabidopsis thaliana* serine acetyltransferase gene in tobacco leads to an increase in the level of cysteine, the level of glutathione and the level of methionine in tissues of transformed
5 plants, compared to control plants. In general, this increase in the amount of free sulphur compounds is associated with transgene expression in the plant cell (Figure 13). Measurement is carried out on leaves from 3 different plants for each homozygous line. The SAT
10 activity is measured as its capacity to promote cysteine synthesis, according to the protocol described above [14].

Expression of the transgene under the control of the constitutive CaMV promoter, causes the SAT
15 capacity (maximum potential enzyme activity measured *in vitro*) to increase by a factor of 2 to 8, compared to the level measured in control plants (plants transformed with an empty vector). To determine the real activity of the SAT transgene, the amount of
20 O-acetylserine (free OAS) was measured. Thus, it was possible to multiply the level of OAS in plant cells (average level of 4 nmol/g of fresh material for control plants, 6 independent measurements) by a factor of 2 to 10, in transformed plants (2 independent
25 measurements). Thus, for most SAT transgenes, associated with the clear increase in the capacity of SAT enzyme activity, is an increase in free intracellular OAS which results from the transgene

activity *in vivo*, and an increase in the amount of free cysteine, compared to control plants (**Figure 14**). The cysteine content in the control plants (PBI) and in the T2 tobacco plants transformed with an SAT (SAT1' and SAT3 lines), is determined as monobromobimane derivatives, by HPLC, for 3 plants per line [33]. The cysteine content of the transgenic lines is increased 2- to 10-fold in comparison with control plants (PBI).

The amount of free cysteine in most transgenic plants which express an SAT is significantly higher, 2 to 10-fold, than the natural level which is measured in control plants PBI (of a value of 5 nmol/g of fresh material, average calculated from three independent lines, each containing 5 plants). This impact of SAT expression is observed as early as the T1 generation. On the other hand, no correlation could be seen between amount of cysteine (and moreover of free OAS) and the SAT activity from transgenes which are measured *in vitro*. On the other hand, a significant positive correlation could be measured between amount of cellular OAS and cysteine level in the cell (**Figure 15**). *In vivo*, a 3- to 10-fold increase, compared to control plants, in the level of free O-acetylserine, which is linked to transgene activity, results in a 3- to 8-fold increase in the level of cysteine in the plants. Analysis was carried out on fully developed leaves (about 2 months) of plants homozygous for the transgene. The control plants are

plants transformed with empty constructs (PBI). An increase in the amount of free cellular OAS which is linked to SAT transgene activity in transformed plants, correlates positively with increase in the amount of cysteine. Thus, an average 6-fold increase in the level of free OAS is associated with a 6-fold increase in the level of cysteine. The slope associated with the distribution of the points is 1.06 ± 0.09 (coefficient of regression 0.67). It indicates that for each molecule of OAS accumulated, one mole of cysteine is synthesized. The value of this slope and the absence of a plateau observed under our experimental conditions, indicate the sulphide formation (assimilation of sulphate and reduction to sulphide) is not a limiting pathway and that SAT activity seems to be the limiting factor in the cell for cysteine formation (**Figure 1**).

The subcellular localization of the SAT1' (truncated form of SAT1) transgene and the SAT3 transgene in transformed tobacco plants was made clear by preparation of the chloroplast fraction of transformed plants which present the highest enzyme activity, compared with PBI plants (controls). The activity associated with the chloroplast compartment is compared with that measured in the total extract (**Figure 16**). The values for serine acetyltransferase activity correspond to 3 lines for the PBI plants (5 plants per line), to 5 lines for SAT1' and SAT3, each

being represented by 5 plants. The columns in grey correspond to the activities measured in the total extract from each of the lines, and the columns in black represent the average of the activities measured in each of the chloroplast preparations.

These results establish definitively that SAT3 is an isoform of the serine acetyltransferase located in the cytosol of plant cells, and that the truncated form of SAT1 (absence of transit peptide) is also located in the cytosolic compartment. With regard to SAT3, these results confirm our interpretations which are derived from analysis of the protein sequence [12].

A direct consequence of increasing the level of cellular cysteine is increased synthesis of glutathione and methionine (see **Figure 1**). Cysteine is destined for multiple usage and besides its incorporation into proteins, and its participation in the synthesis of multiple compounds, such as vitamins (biotin, thiamine, etc. and other sulphur derivatives in the cell), cysteine also participates in the synthesis of glutathione (tripeptide which is associated with numerous plant defence mechanisms and which is considered to be a reservoir for cysteine) and of methionine. Specifically in plants which are transformed with the SAT transgene, the level of glutathione correlates directly with that of cysteine, and is reflected by an increase of 2 to 7 times the

natural level which is measured in control plants (PBI) (Figure 17). The correlation coefficient which is calculated for the distribution of the points is 0.92. A 4-fold increase in cysteine content in transgenic tobacco plants which overexpress SAT results in a 3- to 4-fold increase in the level of glutathione. Analysis was carried out using fully developed leaves (about 2 months) from plants homozygous for the transgene. The control plants are plants which are transformed with empty constructs.

This result indicates that cysteine is the limiting factor in glutathione synthesis in the plant cell. Thus, indirectly, the consequence of any modification of the level of serine acetyltransferase in the cell, will be to increase the amount of intracellular glutathione, by increasing the level of cysteine. This result implies that the transgenic plants obtained have acquired properties of stress resistance compared to the control plants (PBI). This aspect was observed recently ([34] Blaszczyk A. et al., 1999, The Plant Journal 20, 237-243). Moreover, the amount of cysteine and of glutathione which is considered to be a reservoir, brings about increased availability at the time of synthesis of polypeptides rich in cysteine (for example for resistance to phytopathogenic attack), and rich in cysteine and in methionine (for animal foods).

An increase in cysteine in the plant cell also brings about an increase in the relative amount of methionine (**Figure 18**). On the other hand, unlike the results observed for glutathione, the curve has a plateau, which seems to indicate the existence of another control site which would limit methionine synthesis. Moreover, homocysteine, which is derived from the trans-sulphuration pathway, and is the sulphur precursor in methionine synthesis, does not seem to accumulate. This observation thus indicates that the folate pool in the plant cell, which is essential for methylation and for methionine formation, is not a limiting factor. This limitation would thus be situated downstream of cysteine and upstream of homocysteine. It concerns the synthesis of the carbon precursor for the aspartate-derived methionine synthesis (O-phosphohomoserine and/or cystathionine). The level of aspartokinase (the first enzyme of the aspartate pathway for the synthesis of lysine, threonine and methionine) is controlled by several effectors, such as threonine and S-adenosylmethionine (SAM) which comes from methionine synthesis [3]. Cystathionine γ -synthase (see **Figure 1**) is directly regulated at the transcriptional level [3] and, more exactly, methionine or one of its derivatives controls the stability of its messenger [4]. The maximum plateau which is obtained under our experimental conditions is of the order of 39 +/- 7 nmol of methionine/g of fresh material, which

corresponds to a multiplication of the average natural level which is of the order of 6 ± 2 nmol per g of fresh material (PBI control). The maximum value which is obtained for methionine requires an increase in the amount of cysteine in the cell of 4 to 5 times its natural level. The regression coefficient is 0.50.

Moreover, an increase in the methionine in the cells causes the level of *S*-methylmethionine (SMM) to multiply from 2- to 10-fold, according to the plant. SMM is derived directly from the methylation of methionine in the presence of *S*-adenosylmethionine. This compound is important to the cell, and is a form of transport of methyl groups (of methionine) in the plant. In the presence of one molecule of homocysteine (the sulphur precursor in methionine synthesis, and which is derived from cysteine), SMM allows the synthesis of two molecules of methionine ([3], [35], Bourgis et al., 1999, Plant Cell 11, 1485-1497). It may thus have a primordial role at the time of storage protein synthesis in the seed. Moreover, SMM is the direct precursor for the synthesis of compounds such as 3-dimethylsulphoniopropionate which is involved in the resistance of plants to salt stress ([36] Hanson A.D. et al., 1994, Plant Physiol. 105, 103-110). Such an approach has many consequences, in particular for increasing the potentialities of plants on grounds rich in salt.

**Evidence for a regulatory role in the sulphate
assimilation pathway in vivo.**

Serine acetyltransferase is taken to be a limiting factor for the assimilation of sulphur and for the synthesis of cysteine. Its role in bacteria is important since the reaction product, (O-acetylserine, OAS) or its derivative (N-acetylserine), is the effector which modulates the expression of the genes of the sequence of assimilation of sulphur, such as:

- 1, sulphate transport, 2, ATP sulphurylase, 3, APS kinase, and 4, PAPS reductase ([37] Kredich N.M., 1987, in *Escherichia coli* and *Salmonella typhimurium*: cellular and molecular biology, pp. 419-428). In plants, a role has been shown for OAS in modulating the expression of several genes, which concerns sulphate transporters, ([38] Smith F.W. et al., 1997, *The Plant Journal* 12, 875-884; [39] Hawkesford M.J. et al. 1995, *Z. Pflanzenernährh. Bodenk.* 158, 55-57; [40] Clarkson D.T. et al. 1999, *Plant Physiol. Biochem.* 37, 283-290), ATP sulphurylase [39-40] and APS reductase ([41] Neuenschwander U. et al. 1991, *Plant Physiol.*, 97, 253-258). The role of serine acetyltransferase activity in gene modulation has been proposed based on the kinetics of the cysteine synthase complex (bienzyme complex composed of serine acetyltransferase and of O-acetylserine (thiol) lyase) ([41] Droux et al. in *Sulphur and Nutrition in Plants*, in press), and has led to the description of a model to describe the mechanism

of gene regulation. The role of OAS is also determinant in the regulation of gene expression during seed formation ([42] Kim H. et al., 1999, *Planta* 209, 282-289).

- 5 In transgenic plants which overexpress an SAT in the cytosol, a transient increase in OAS was shown (increase of 2 to 10 times its natural level, see **Figure 15**). In parallel, in most transgenic plants, an increase in OASTL activity was measured (**Figure 19**).
- 10 This increase of 2 to 5 times compared to the activity which is measured in PBI controls, concerns only the chloroplast-associated activity. Moreover, in a Western Blot, the signal which is observed is stronger in most transgenic lines (**Figure 20**), indicating that the
- 15 increase in activity corresponds to an induction of *de novo* synthesis of OASTL. This original result corresponds to the first demonstration of the role of OAS (*in planta*) in the modulation of genes of the sulphate assimilation pathway, in particular for
- 20 chloroplast OASTL.

- Referring to **Figure 20**, an equivalent amount of protein (0.150 mg) undergoes SDS-PAGE (12%), and after separation, the proteins are transferred onto a nitrocellulose membrane. The presence of OASTL is
- 25 revealed by incubation with antibodies which have been raised against chloroplast OASTL from spinach leaves [7].

free amino acids). It is reflected by a drop in this relative ratio, due to the enrichment in total sulphur compounds (cysteine, methionine, SMM and glutathione). This factor is important since it conditions the

5 polypeptide content of the seeds, and leads to enrichment (or impoverishment if the N/S ratio is too high) of storage proteins which are rich in sulphur-containing amino acids, to the detriment of polypeptides which are lacking in these compounds.

Example 12. Analysis of OTP-SAT3 (OTP-SAT1') transgenic plants

Analysis of transformants at the TO stage of transgenic plants which express a cysteine-insensitive

15 SAT (here for example, SAT3 or SAT1'; truncated form of SAT1 U22964), in leaves or in seeds (under the control of a seed-specific promoter), reveals an increase in free cysteine content, but also in glutathione content (2.6 times the natural level), and in methionine

20 content. Plants which express these same isoforms in the cytosol under the control of a seed-specific promoter show a level of sulphur compounds which is higher than in control plants.

Example 13. Analysis of results for SAT1 (cDNA U22964 or SAT1jw, transit peptide form) transgenic plants and control plants.

- The impact of expression of serine
- 5 acetyltransferase in mitochondria was analysed by transforming plants with the construct (**Figure 12**) which contains the entire SAT1 sequence. Analysis of plants at the T0 stage makes it possible to show an increase in free cysteine in the cell (**Figure 21**).
- 10 Analysis is carried out on leaves which are formed before appearance of the floral scape. The fourteen lines show a 2- to 6-fold multiplication in cysteine level, compared with the control plant (PBI).

- The increase in cysteine is accompanied by a
- 15 general effect on the amount of sulphur compounds, with a 4-fold multiplication in the amount of glutathione in the cell (**Figure 22**). Unlike the case of SAT expression in the cytosolic compartment, the general appearance of the distribution of values in the
- 20 different lines, shows a plateau which would indicate limitation in glutathione synthesis. This limitation may concern the level of glutamate and/or glycine or may concern glutathione control of its own synthesis (retroinhibition of one of the enzymes which
- 25 participate in glutathione synthesis, enzyme E6 and/or enzyme E7 see **Figure 1**).
